1 DESCRIPTION OF ANALYSIS UNDERTAKEN

Many of the factors we are interested in are related to each other as well as being related to
cognitive ability. For example, younger mothers are more likely to have lower qualifications,
to be lone parents, and to live in areas of high deprivation. Simple analysis may identify a
relationship between maternal age and cognitive ability. However, this relationship may be
occurring because of the underlying association between maternal age and education. Thus,
it is actually the lower education levels amongst younger mothers which is associated with a
greater likelihood of lower cognitive ability in their children rather than the fact that they are
younger in age. To avoid this difficulty, multivariate regression analysis was used. This
analysis allows the examination of the relationships between an outcome variable and
multiple explanatory variables whilst controlling for the inter-relationships between each of
the explanatory variables. This means it is possible to identify an independent relationship
between any single explanatory variable and the outcome variable; to show, for example,
that there is a relationship between maternal age and cognitive ability that does not simply
occur because both education and maternal age are related.

The regression models developed for this report were fitted with standardised ability score at
age 5 as the outcome variable. The equivalent measure at age 3 was included as an
explanatory variable. Measures of parental education and the additional factors identified
from the literature were also added as explanatory variables. By including a measure of
ability at age 3, the results of this analysis identify characteristics which are associated with
a change in assessment score between ages 3 and 5, after controlling for parental level of
education and other, potentially confounding, characteristics.

1.1 Stage 1: Analysis of key social background factors associated with
change in cognitive ability

Tables 1 and 2
Household equivalised income, parental level of education and socio-economic classification
were included as explanatory variables in a single regression model alongside standardised
ability score at age 3.

1.2 Stage 2: Domain-based analysis of factors associated with change in
cognitive ability

Tables 3 to 18
The measures identified were added as explanatory variables to a linear regression model
alongside standardised ability score at age 2 and parental level of education, with score at
age 4 as the dependent (outcome) variable. Separate models were run for vocabulary and
problem solving and for each domain. Those variables found to be significant in the
individual within-domain models were then added to a final, cross-domain model. This
analysis permits the examination of the independent effects of each factor on change in
cognitive ability, whilst holding the effects of other confounding factors – including level of
parental education – constant. In addition, by considering the effect of factors in each
domain on the relationship between parental level of education and the outcome variable,
and the level of variance explained by the model, it is possible to measure whether the
additional factors help explain some of the education-related differences.
The effect of factors in each domain was explored using multivariate analysis. The results of this analysis allow us to determine which characteristics, circumstances and experiences of children’s lives were independently associated with a relative improvement or decline in cognitive ability in the pre-school period after controlling for level of parental education. In addition, by looking at whether and how these factors affect the relationship between parental level of education and cognitive ability at age 4 (by considering any change in the strength of the regression co-efficient), and considering how much of the difference in ability the combination of characteristics help explain when added to the model, it is possible to measure whether variations in the additional factors are behind some of the education-related differences. That is, for example, to demonstrate whether some of the difference in ability by parents’ education actually occurs as a result of differences in parenting practices amongst parents with different levels of education.

1.3 Stage 3: Combined domain analysis of factors associated with change in cognitive ability

*Tables 19 and 20*

The next stage of analysis involved entering the significant domain factors together into a single regression model for each ability alongside parental level of education. In so doing, this analysis explores the extent to which each factor remains independently associated with change in ability and an examination of the combined effect of all factors on the relationship between education and change in ability.

1.4 Stage 4: Sub-group and interaction analysis

*Sub-group analysis: tables 21 to 24
Interaction analysis: tables 25 and 26*

1.4.1 Description

For the sub-group analysis, the final combined domain models were run first, on a sub-sample of degree-educated parents, and then on a sub-sample of parents who had no qualifications, lower-level Standard Grades (or equivalent) or upper-level Standard Grades (or equivalent).

For each interaction, three models were run. One including an interaction between the explanatory variable and degree-level qualification, one including an interaction between the explanatory variable and no or lower-level qualifications, and one included both the degree-level and no or lower-level qualification variables. This permitted an exploration of the impact of different education reference groups. In the first, the reference group is all those who do not have a degree; in the second all those with qualifications at Higher grade level or above; in the third all those with Higher grades (or equivalent).

The results of the interaction analysis are summarised in Table 25 and Table 26. Where the interaction is significant this indicates that the relationship between the explanatory variable and change in development ability is different according to parental level of education. Whilst there were only a small number of statistically significant results suggesting that, overall, most of the relationships between the explanatory variables, this does provide some evidence amongst the circumstances and experiences considered in this paper of factors which could be influenced by policy in order to help improve the development of cognitive ability amongst children from poorer educational backgrounds in order to narrow the ability gap in the pre-school period.
1.4.2 Interpretation: knowledge of vocabulary

So far as change in vocabulary ability is concerned, maternal age shows some difference in impact across different educational groups. In the main model, maternal age was not statistically significant, although the relationship between having a mother aged under 25 and change in ability was negative. However, the interaction results suggest that there appeared to be some positive effect of being a younger mother in the lower educational group. This is likely to reflect the temporal nature of the qualification data in that younger mothers are, by the very fact that they are younger, considerably less likely to have had the chance to obtain qualifications at further and higher education levels. Thus lack of educational qualifications amongst younger mothers may be of less significance than a lack of qualifications amongst older mothers.

The relationship between infant-maternal attachment and change in vocabulary ability also shows some variation by level of parental education. The results from the main regression model suggested that children who experience better attachment are more likely to show a relative improvement in their vocabulary in the pre-school period. In this instance, the interaction indicates that attachment has a significant positive effect on the vocabulary development, in particular, of children whose parents have lower qualifications. The effect is not significant for children whose parents are degree-educated. This implies that the negative effect on cognitive development associated with a lack of parental qualifications can be mediated by improving early infant-maternal attachment. The benefits of good attachment on cognitive development compensate for and protect against, in some part, the parents' lower education level.

A revised interaction was included between education and communicative development at 22 months using an adjusted lower qualifications group restricted to only those with no qualifications or lower level Standard Grades\(^1\). This adjusted interaction was statistically significant and positive. This suggests that the significant positive relationship between early communication skills and relative improvement in vocabulary between ages 2 and 4, seen in the main model, was more pronounced for children whose parents had no or lower qualifications. Thus better early communication ability is more predictive of later relative improvement in language skills for children from worse educational backgrounds. This finding has a number of implications. First, it suggests that the children from worse educational backgrounds whose relative vocabulary ability improves in the pre-school period are those who were already demonstrating more advanced communication skills at an earlier age. Secondly, it implies that for children whose parents have no or lower qualifications, poor early communication skills will likely persist through the pre-school period with little or no relative improvement. Third, and in contrast, there is a suggestion that in those families where parents have higher qualifications, a child's lack of advanced early communication skills does not necessarily prohibit later improvement in vocabulary in the same way it does for children whose parents have no or lower qualifications.

Put simply children from better educated backgrounds who underperform in early communication appear more able to 'catch-up' than their underperforming peers from lower education backgrounds who, instead, are more likely to see their relative ability deteriorate. However, if children from households with lower parental education levels are already demonstrating good communication skills at an earlier age, this mediates the more negative effect of educational background on later ability. Thus it would appear that targeted early

\(^1\) There were no statistically significant interactions between the education and communicative development at 22 months using the existing education banded groups. Yet, when these interactions were added to the model, all of the existing associations between the early communication measure and change in vocabulary, seen in the main model in Table 3.13, disappeared completely as did the effects of education. This suggested that some interaction was occurring but not at the level we were currently measuring.
intervention to maximise the successful communicative development of children in this group in the first two years of their lives will benefit their language development in later years. Leaving the remediation of language ability until the pre-school period would appear to be too late for those children from worse educational backgrounds.

None of the interactions between education and ante-natal class attendance were significant suggesting the positive effect of attending ante-natal classes on ability development between 3 and 5 is similar irrespective of parental education. Thus ante-natal classes appear to have a ‘universal’ effect. However, it is not possible to say whether it is attendance at the classes in itself which is driving the difference. The cross-sectional analysis detailed in section 3 of the main report illustrated the stark variation in ante-natal class attendance by parental level of education. Whilst our analysis has demonstrated the effect of class attendance is independent of parental education, it is feasible, and perhaps likely, that attendance at ante-natal classes is instead measuring characteristics, attitudes and experiences associated with a desire to be a good parent which are also beneficial to the improvement of vocabulary ability in the pre-school period.

The interaction between breastfeeding and degree-level education is shown to be significant and positive. This suggests that the relationship between breastfeeding and the continuing development of vocabulary ability in the pre-school period is primarily for better educated parents. Thus whilst breastfeeding is known, from existing GUS research and research elsewhere (Iacovou and Sevilla-Sanz, 2010), to be associated with higher cognitive ability, encouraging mothers from lower educational backgrounds to breastfeed does not appear to offer a means of reducing the gap in vocabulary ability specifically during the pre-school period. Again, as with ante-natal classes, we do not have sufficient information to determine whether it is the experience of breastfeeding itself which leads to improvement in vocabulary ability in the pre-school period or some other characteristics of mothers most likely to breastfeed not included in the model, but represented by the act of breastfeeding. What is clear is that breastfeeding, or the parenting behaviour it is measuring, has an effect independent to that of education.

1.4.3 Interpretation: problem solving

In respect of change in problem solving ability, the interaction between the frequency of home learning activities and lower qualifications was significant and positive. It appears, therefore, that a good home learning environment – as measured by the frequency of parent-child activities such as reading, drawing, and singing nursery rhymes etc – at the ages of 2 and 3 has more benefit in respect of the relative improvement of problem solving ability for children whose parents have lower qualifications. Children from lower education households who experience a higher frequency of such activities are more likely to improve their relative problem solving skills in the pre-school period than children who have a lesser experience of this. Bromley (2009) reported a relationship between a higher frequency of child activities and higher cognitive ability at age 3, after controlling for parental education. What the positive interaction in further suggests is that although children from lower educated backgrounds may have lower than average problem solving skills to start with (at age 3), those who experience a higher frequency of parent-child activities see that ability continue to improve during the pre-school period in the face of an overarching trend for children in this sub-group of ability deteriorating, relative to their peers, during this time.

On the whole, missing out on pre-school is detrimental for the development of problem solving ability. Those children who did not attend tended to show a relative deterioration in their problem solving ability in the 2-4 period. However, as the interaction between no pre-
school and degree education of the parents was significant and the co-efficient was positive, this suggests that for children with degree-educated parents missing pre-school is not necessarily detrimental to their problem solving ability. Given the very small size of the group of children who did not attend a pre-school place, it is not possible to draw any strong conclusions from these findings.

None of the remaining interactions included in the problem solving analysis – attending a private pre-school, starting primary school, being breastfed and living in an area in the most deprived quintile – were significant. This indicates that the relationship between these factors and change in problem solving ability does not vary according to parental level of education. Whilst it may be taken as encouraging that private pre-school attendance and early primary school experience appear to lead to a general improvement in problem solving ability, these factors do not appear to offer a policy solution for narrowing the cognitive gap and improving, in particular, the ability of those children whose parents have lower qualifications.
2 REGRESSION TABLES

2.1 Interpreting linear regression coefficients

In each output table included below, four items are included: unstandardised coefficient, standardised coefficient, the p-value (significance value) and the 95% confidence intervals for the unstandardised coefficients.

The unstandardised coefficients tell us by how much the value of the outcome or ‘Y’ variable (standardised cognitive ability at age 5) increases (when the coefficient is positive) or decreases (when the coefficient is negative) when the value of the independent or ‘X’ variable increase by 1 unit and the value of all other independent variables (IVs) in the model are held constant. Since the independent variables all have different scales, we cannot compare the relative importance (or strength) of the unstandardised coefficients.

However, it is possible to compare the relative importance of the variables by looking at the standardised coefficients. These are the partial regression coefficients when all independent variables are expressed in standardised form. A larger positive figure indicates a stronger positive relationship between the independent variable and the outcome variable. A lower negative figure indicates a stronger negative relationship between the independent variable and the outcome variable.
